## Abstract

The language that individuals use for expressing themselves contains rich psychological information. Recent significant advances in Natural Language Processing (NLP) and Deep Learning (DL), namely *transformers*, have resulted in large performance gains in tasks related to understanding natural language. However, these state-of-the-art methods have not yet been made easily accessible for psychology researchers, nor designed to be optimal for human-level analyses. This tutorial introduces *text* (<https://r-text.org/>), a new R-package for analyzing and visualizing human language using *transformers*, the latest techniques from NLP and DL. The *text-package* is both a *modular solution* for accessing state-of-the-art language models and an *end-to-end solution* catered for human-level analyses. Hence, *text* provides user-friendly functions tailored to test hypotheses in social sciences for both relatively small and large data sets. The tutorial describes methods for analyzing text, providing functions with reliable defaults that can be used off-the-shelf as well as providing a framework for the advanced users to build on for novel pipelines. The reader learns about three core methods: (1) *textEmbed()*: to transform text to modern transformer-based word embeddings; (2) *textTrain()* and *textPredict()*: to train predictive models with embeddings as input, and use the models to predict from; (3) *textSimilarity()* and *textDistance()*: to compute semantic similarity/distance scores between texts. The reader also learns about two extended methods: (1) *textProjection()/textProjectionPlot()* and (2) *textCentrality()/textCentralityPlot()*: to examine and visualize text within the embedding space.

## Translational Abstract

Natural language is the fundamental way individuals communicate their thoughts and emotions to others. Recent advances in Artificial Intelligence (AI), referred to as *transformers*, have resulted in large increases in performance at most tasks related to understanding natural language. This tutorial introduces how to use these state-of-the-art AI techniques in both custom research analyses as well as in completely end-to-end analytic processes. We describe *text*, a software package which provides transformer-based techniques intended to be easily accessible for social scientists. The *text-package* is *open-source*, written for the statistical programming language *R*, and it is free to use or alter. It comprises user-friendly functions to transform text to numeric representations, that are used for examining their relationship to other variables or for visualizing statistically significant features of texts. Transformers can facilitate analyses of natural language for gaining psychological insights with unprecedented accuracy and provide a more detailed understanding of the human condition.

How individuals express themselves and their state of mind with natural language constitutes a wealth of information for understanding them psychologically and socially (e.g., see Kern et al., 2016; Kjell et al., 2019). “Language is the most common and reliable way for people to translate their internal thoughts and emotions into a form that others can understand” (Tausczik & Pennebaker, 2010, p. 25). This tutorial explains how psychology researchers can use recent advances in Artificial Intelligence (AI), including Natural Language Processing (NLP) and Deep Learning, to quantitatively analyze natural language.

Researchers in NLP have turned to open-vocabulary methods that rely on patterns in linguistic data to derive models of language. These methods leverage the idea that words may be represented by values based on how they co-occur in languages (e.g., Firth, 1957), and allow for modeling words according to the contexts in which they appear, rather than relying on a priori assumptions about word-category relations resulting in extremely powerful models of language. In fact, the latest version of such models, the deep learning-based *transformers*, have led to nothing short of a transformation in the AI field concerned with language: Natural Language Processing. Researchers have called for the use of these language models to gain psychological insights (e.g., Eichstaedt et al., 2021).

The transformers method has universally increased the accuracy of AI techniques for processing language. For example, the transformer-based model GPT-3, by OpenAI, is writing documents believed to be authored by humans (Brown et al., 2020); and BERT (Bidirectional Encoder Representations from Transformers; Devlin et al., 2019), the first widely used, general purpose transformer network developed by Google, has already been referenced in over 16,000 scholarly works in a period of only 2 years.<sup>1</sup>

The key to transformers’ success is that such models can represent words differently according to the context they are in. BERT was released by Google and has been integrated into its Search function; now it actually understands the difference between “travel from Sweden to New York” and “travel from New York to Sweden” (Nayak, 2019). This tutorial aims to make these methods easily available to a broad audience within social and behavioral sciences; as well as further developing and optimizing them for human-level analyses. These state-of-the-art word embeddings may be used to examine their relationships to (i.e., predict) numerical variables, compute semantic similarity to other texts, or visualize (statistically significant) words in various dimensions within the word embedding space.

For this discussion, the type of data may broadly be categorized into two (overlapping) types: First, *everyday occurring language*, which, for example, include gaining insights from analyzing recordings of spoken language in relation to emotional fluctuations throughout the day (Sun et al., 2020); and social media text (Park et al., 2015) to predict both physical (Eichstaedt et al., 2015) and psychological (Eichstaedt et al., 2018) outcomes. Examining naturally occurring language may also include analyzing emails, letters, blogs, text messages, medical journals, speeches, diaries, song texts, voice recordings etc., though one must consider ethical and privacy issues when analyzing such text.

Second, probed *language* involves probing or asking participants to answer questions with spoken or written language. These types of data have, for example, been used to measure and describe psychological constructs through probed language-based

assessments as a complement to traditional rating scales (Kjell et al., 2019, 2022), and analyze written narratives of traumatic life events to predict health related outcomes (Campbell & Pennebaker, 2003; Son et al., 2020). Probed language may also involve asking participants to recall various memories, describe themselves in various ways, partake in stream-of-consciousness tasks and so on.

In addition, language may be generated within an experimental context. Computational language methods can, for example, be used to enhance experimental control by matching word stimuli according to semantic similarity (Dougal & Rotello, 2007; Gagné et al., 2005), examining the text generated from experimental manipulations (Garcia & Sikström, 2013) and using semantic similarity of the names of objects to find significant correlations with neural organizations in the brain (Carlson et al., 2014). The multitude of applications of computational methods highlights its potential and flexibility as a research method.

This tutorial covers methods in an R-package called *text* (<https://r-text.org/>) to carry out the use of transformers for psychological research. The *text-package* is an open-source library comprising tools for analyzing and visualizing various features of texts; both in relation to other texts as well as numerical variables. The package makes state-of-the-art NLP, statistics, and ML techniques available to R users, with functions particularly targeting social scientific applications. To map words to numeric representations, *text*-functions transform texts to word embeddings using transformer-based pretrained language models. This tutorial assumes very basic knowledge of R (R Core Team, 2022); so, for a free, beginners tutorial see *R for Data Science* by (Grolemund & Wickham, 2018).

## Objectives and Aims

The *text-package* incorporates two main objectives. First, to serve R-users as a *point solution* for converting text to contextual word embeddings—numeric representations of words—using a state-of-the-art AI technique called *transformers*. These word embeddings may be used for a large variety of tasks in the user’s own analyses (pipeline). The second objective is to serve as an *end-to-end solution*, where *text* provides powerful and accessible functions for analyzing and visualizing text in relation to other text and numerical variables. This tutorial describes both core and extended functionalities. Core functionalities are based on standard methods with empirical support, including: (a) transforming text to word embeddings, (b) predictive modeling with word embeddings, and (c) computing semantic similarity scores between text. The extended functionalities are less well-established, novel methods, aimed at supporting the core functionalities, including (a) visualizing words’ position in the embedding space. The objective of the *text-package* is to balance user-friendliness and flexibility while simultaneously empowering with advanced analyses. Accessibility is reflected in functions with reliable default settings selected by experts in the NLP fields so that those with no experience can use out of the box settings to test their research hypotheses. Further, visualizations aim to make it easy to understand what is going on in the analyses; for example, displaying actual word embeddings and tokens, plotting words, or viewing cross-validated predictive results.

<sup>1</sup> Google Scholar accessed March 11, 2021.

## Current Alternatives

There are few alternatives in R (R Core Team, 2022) that focus on getting state-of-the-art word embeddings; and that have functionalities tailored for analyzing embeddings in downstream tasks relevant for social sciences and psychological research. Computer scientists have predominantly used Python (Van Rossum & Drake, 1995), and Python-libraries such as the Differential Language Analysis ToolKit (DLATK; Schwartz et al., 2017), PyTorch (Paszke et al., 2019), spaCy (Honnibal, & Montani, 2017), and NLTK (Bird et al., 2009). Further, even though computer scientists use Python for standard NLP/ML tasks, few python packages attempt to bridge this line of work with psychological research such as DLATK. The *text-package* comprises an interface with Python to get the state-of-the-art language models while also conceptually building on DLATK, and drawing on experiences learned from that project (here also see the web-application Semantic Excel; Sikström et al., 2018).

There are some R-packages that allow for text mining (e.g., see *tm* [Feinerer & Hornik, 2019], *tidytext* [Silge & Robinson, 2016], and *quanteda* [Benoit et al., 2018]) and for various automatic coding procedures of text responses (see *shinyReCoR*; Andersen & Zehner, 2021). To our knowledge, there is only one other R-package that enables the transformation of text to word embeddings (RBERT; an R implementation of BERT; Bratt & Harmon, 2020); however, it does not come with functions to use these word embeddings including ML techniques. Additionally, *text* comprises functions tailored for small data as well as big data. Whereas other R-packages focus on text mining of big data, *text* enables transformer-based embeddings as well as analyses of relatively small data sets, which is often common in social and behavioral sciences.

## Installation of *Text*

The *text-package* can be downloaded and installed from CRAN or Github. The *text-package* uses an R-package called *reticulate* (Ushey et al., 2020) as an interface to Python (Van Rossum & Drake, 1995) and the Python packages *torch* (Paszke et al., 2019), *transformers* (Wolf et al., 2019), *nlk* (Bird, Klein, & Loper, 2009), and *numpy* (Oliphant, 2006). It is important to get versions of these libraries to work together. The *text-package* includes functions that help you set up an environment with the correct versions of these packages for your specific OS (that is tested for Linux, MacOS, and Windows).

This tutorial was written for text Version 1.0. Tutorial data, models and code can be retrieved at the open science framework at: <https://osf.io/dgczt/>, where we will update the code for future versions of the *text-package*. To install the *text-package* run:

```
# Install text from CRAN
install.packages("text")
library(text)

# Set-up an environment with text-required python packages
textrpp_install()

# Initialize the environment – and save the settings
for next time
textrpp_initialize(save_profile = TRUE)
```

If you experience problems with the installation, see the extended installation guide for up-to-date information ([https://r-text.org/articles/Extended\\_Installation\\_Guide.html](https://r-text.org/articles/Extended_Installation_Guide.html)).

## Core Functionality

The *text-package* has three core functionalities: (1) transforming text to word embeddings, (2) predictive modeling with word embeddings, and (3) comparing words or texts for semantic similarity. These are described below, followed by the introduction of two extended functionalities.

## Transforming *Text* to State-of-the-Art Word Embeddings

NLP is concerned with automatically processing and making sense of digitized human language (for a broad and detailed treatment of NLP methods see Jurafsky & Martin, 2020). The idea that each word in human languages may be represented by numeric vectors dates back at least to the 1950s (e.g., see Firth, 1957; Osgood et al., 1957). Despite its long history, the field of NLP has undergone a sort of revolution over the past 3 years, seeing substantial advances in the state-of-the-art. These advances span over nearly every common task that NLP attempts to solve including syntactic parsing, sentiment analysis, question answers, and machine translation. All advances are tied to a single method: *transformers* (Devlin et al., 2019; Rogers et al., 2020; Vaswani et al., 2017).

The *text-package* implements these advances to enable the user to access many state-of-the-art pretrained language models. In this next part, word embeddings are described in more detail, followed by a demonstration on how the *text-package* transforms text data into word embeddings. These word embeddings are later used in down-stream tasks to provide examples of how they may be used, including predicting psychology related outcomes (e.g., psychological rating scale scores), and examining similarity in meaning between texts. Hence, word embeddings may be seen as the backbone of most *text*-functions.

## Word Embeddings

A word embedding is a list of values (an ordered *vector*) that aim to numerically represent the meaning of a word. A word embedding normally comprises several hundred numbers; so that a word is represented by many dimensions. The numbers may be seen as coordinates in a geometric space that comprises several hundred dimensions (a high dimensional space). The closer two words are in this space (i.e., the more similar their *vector* embeddings are), the more similar the words are expected to be in meaning. In other words, embeddings capture the relationships between words, where proximity in the high dimensional embedding space signifies similarity in meaning. To represent several words, sentences and paragraphs, word embeddings may be aggregated. The aggregation can, for example, be through the mean, maximum or minimum of each dimension of the word embedding.

To train word embeddings with high quality requires a lot of text data; where the approaches use the statistical patterns of *how* words are used. “You shall know a word by the company it keeps” (Firth, 1957, p. 11) is a core rationale underlying the creation of

word embeddings. Words within natural language are *not* randomly distributed, instead contextual words are predictable and define its meaning (Iliev et al., 2015). Hence, it is possible to use this distribution to represent “the meaning of a word through the contexts in which it has been observed in a corpus” (Erk, 2012, p. 635). This may be achieved by constructing a table of word co-occurrence counts, where the dimensions are extracted using a dimension reduction technique such as the Singular Value Decomposition (Golub & Kahan, 1965). Practically, the first column of the frequency table may hold the words in a natural language, the first row may hold word contexts (such as documents of texts) and the rest of the cells hold the co-occurrence counts/frequency. Ultimately, the words are represented by a vector containing a number for each extracted dimension. Note that these types of approaches are referred to as *unsupervised*, as no predefined categories or judges are used to produce the numeric representations.

### Decontextualized Word Embeddings: A Bag of Words

Decontextualized word embeddings (or *semantic representations* as they were called) do not account for the context a word was in. Earlier methods were unable to capture the order that words appeared in, so that words in a text were treated as a bag of scrambled words: Bag of words (BOW) models (see Figure 1). The word embedding is

*static* (or decontextualized), so that the embedding for “happy” is always the same even if it appeared in the context of “I am happy” versus “I am not happy.” Examples of commonly used decontextualized approaches include word2vec (Mikolov et al., 2013), Latent Semantic Analysis (LSA; Deerwester et al., 1990) and Latent Dirichlet allocation (LDA; Blei et al., 2003).

### Contextualized Word Embeddings and Word Order

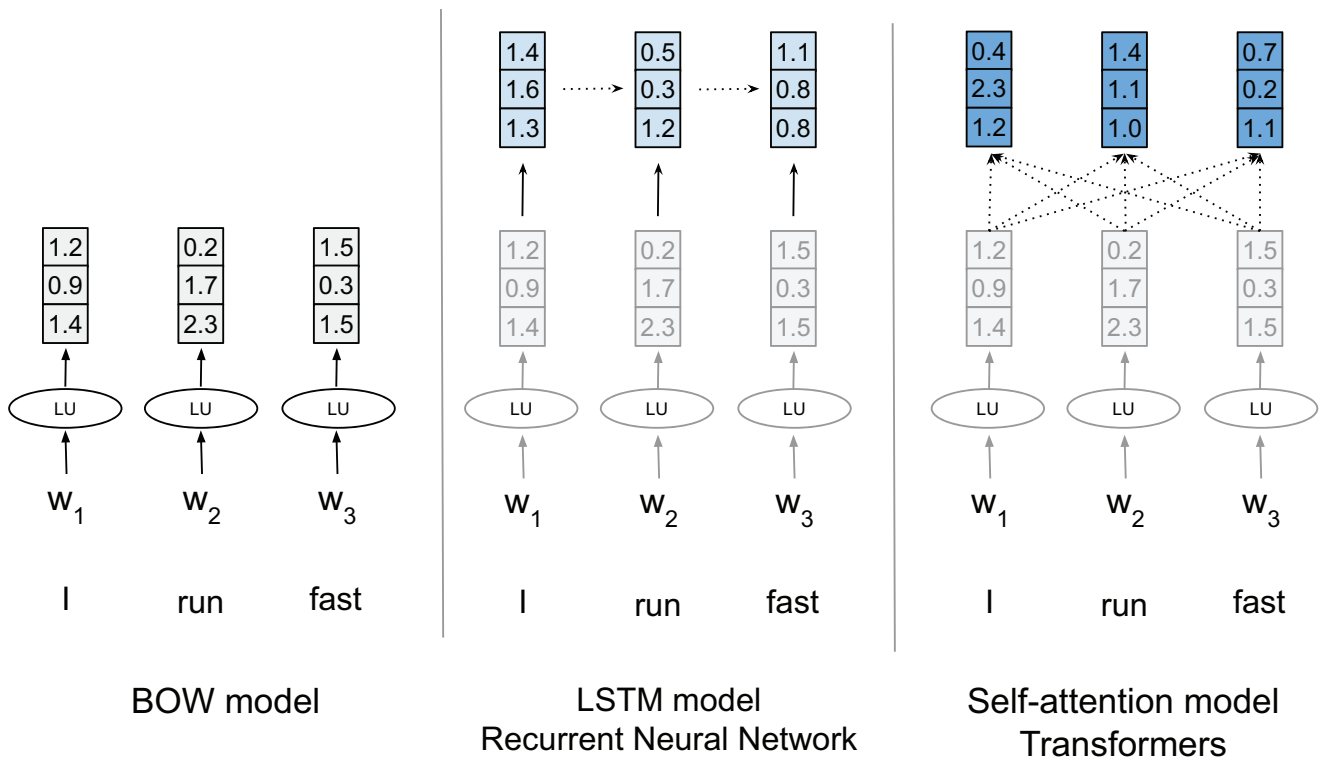

Contemporary NLP algorithms aim to extract the latent meanings in text. These algorithms are based on deep neural net (or deep learning) architectures to construct contextualized word embeddings, using decontextualized word embeddings as input (e.g., see BERT; Devlin et al., 2019). When using these algorithms, a word’s embedding is different depending on the context it was in and the order of the words in the context—this is achieved by enabling the word embedding to be influenced by other word embeddings in the context through a mechanism referred to as self-attention.

### The Deep Neural Network Architecture: The Layers and Hidden States

As a deep learning transformer model, BERT comprises several layers. *Hidden states* refer to the output of each layer; these may

**Figure 1**

*An Illustration of How Information is Connected Within the Output of Different Language Model Architectures*

*Note.* The BOW model is how traditional word embeddings, such as those from latent semantic analysis (LSA) or word2vec, are typically applied: there is no notion of capturing word order or adjusting the individual word representations in light of the other words. LU = Look-up; the circles describe a mechanism that looks-up words’ non-contextualized embeddings. BOW = bag of words (i.e., no transformations beyond non-contextualised embeddings); LSTM = Long Short-Term Memory;  $w$  = word; squared symbols = word embeddings; gray = decontextualized word embeddings; stronger shades of blue indicate more contextualized word embeddings. See the online article for the color version of this figure.

be aggregated across layers to a word embedding that represents each word (or sentence). The use of multiple layers enables the models to capture nonlinear relationships. BERT-base comprises 12 layers, whereas BERT-large comprises 24 layers; where each layer comprises numeric values for each dimension, which for BERT is 768 dimensions. Hence, with BERT-large one token can be represented with 18,432 ( $24 \times 768$ ) values. There are several ways to make use of these layers: including only using one of the layers or concatenating them to one longer embedding.

It is not yet fully understood how the various layers differ; and the advice on how to best use them differs. In short, empirical examinations indicate that “BERT’s intermediate layers encode a rich hierarchy of linguistic information, with surface features at the bottom, syntactic features in the middle and semantic features at the top” (Jawahar et al., 2019, p. 1). Further, it has been demonstrated that later BERT layers are more context specific (Ethayarajh, 2019). Later we discuss how to use these layers in human level tasks.

### Self-Attention

Transformer’s deep neural net architecture has the *self-attention* mechanism at its core (Vaswani et al., 2017). It is self-attention that enables the model to combine information about surrounding words at varying degrees. Thus, each surrounding word can influence the word embedding of the target word. In other words, self-attention enables the algorithm to incorporate the embeddings of other words’ embeddings in so far as it produces a more robust representation of the target word. The self-attention mechanism puts *different* attention or weight to different word embeddings from the context depending on which appear to be most relevant. During training, the transformer-based models have learned how to parameterize the attention layers to amplify the influence of the most relevant parts of a context.

The transformers’ self-attention mechanism may be compared with previous models such as Long Short-Term Memory models (LSTM; Hochreiter & Schmidhuber, 1997). These models are based on recurrent neural networks, where the influence of the context mechanism is less pervasive than in transformers. In LSTM the influence of the context is only based on the previous *state*—the embedding of the word just to the left of the target word, which in turn was influenced by its surrounding words, and so on. The model can also be run across the sequence backward, such that the previous *state* is an embedding of the word to the right. However, it still requires for nonadjacent pairs of words to pass information about each other through the embeddings between them rather than directly. With self-attention *all* words are connected with the potential to influence each other’s meaning through the word embeddings. The transformers can model the dependency of every two words in a text sequence and are also suitable for long range dependencies. The architecture of the transformers also reduces the amount of sequential computational steps compared with previous contemporary models such as LSTMs; and this results in decreased information loss and faster training times through parallel processing (Wolf et al., 2019).

These descriptions are at a very high level aimed to provide the reader with a sufficient understanding to be able to make use of the key functionality of transformers: turning text into feature vectors (embeddings). There are many recent papers specifically

introducing deep learning with a focus on Natural Language Processing (e.g., see Lauriola et al., 2022), in length discussing the opportunities and risks of using these models (Bommasani et al., 2021) as well as reviews/surveys providing a broader overview and deeper understanding about various model architectures of neural networks such as recurrent, recursive, convolutional, and attention models (Babić et al., 2020; Otter et al., 2019; Qiu et al., 2020), and specifically focusing on the BERT models (Rogers et al., 2020).

### Performance of BERT

Devlin et al. (2019) demonstrated that BERT obtains substantial improvement on a wide range of NLP tasks. For example, it achieved a 7.7% point absolute improvement on the language understanding tasks called GLUE (General Language Understanding Evaluation); and a 4.6% absolute improvement accuracy on the MultiNLI (the Multi-Genre Natural Language Inference corpus, which comprises several hundred thousands of sentence pairs).

### Accessible Pretrained Language Models in Text

To get contextualized word embeddings for your text data, the *text-package* connects with HuggingFace’s *Transformers* library (Wolf et al., 2019) in Python. This enables the users to implement many state-of-the-art *pretrained* language models, including XLnet (Yang et al., 2019), RoBERTa (Liu et al., 2019), and ALBERT (Lan et al., 2019). As the name suggests, a pretrained model has already been trained on other data; so that the model can be applied to your text to retrieve high-quality embeddings. This is good considering that training a high-quality deep learning language model requires a lot of computational resources; Wolf et al. (2019) point out that RoBERTa was trained on 160 GB text, and that training this on a typical cloud computing service would cost around 100K USD. Consequently, some models have been developed with the focus of being smaller and requiring less computational resources to be trained (e.g., see DistilBERT; Sanh et al., 2019), whereas others have had the focus on achieving improved performance (e.g., XLNet; Yang et al., 2019).

Some models include multiple languages such as multilingual BERT (mBERT), which is trained on text from the top 104 languages with the largest Wikipedia entries. Hence, the same model includes several languages, where similar languages (e.g., Germanic, Slavic) are found close to each other in the embedding space (Libovický et al., 2019). mBERT is found to learn cross-lingual word alignment with high-quality (Libovický et al., 2019). The *text-package* implements these multilingual models.

### Model and Word Embedding Specifics

Different models may be based on different types of (domain) text, and use different tokenization (described in detail below), number of layers and hidden states. It is useful to consider these aspects when selecting an appropriate model and its settings, although default settings in *text* will often achieve apt results.

**Type of Domain Text Used in Pretraining.** Word embeddings become better when there is high domain similarity between the text used to create the language model and the text that should

be interpreted/used for down-stream tasks. To create models for a narrow domain can however be challenging because pretrained models require large quantities of text data (and computational resources). Nevertheless, it is worth thinking about the type of text used to train the models, and how that might influence your results. BERT was originally trained using Wikipedia text; however, other BERT models have been fine-tuned on clinical text (Alsentzer et al., 2019) and scientific text data (Beltagy et al., 2019). These and many more models are available through the *text-package*.

**Uncased Versus Cased Models.** *Uncased* models convert all words to lowercase, whereas *cased* models keep the casing of the text. Select a *cased* model if you think that letter casing will be helpful for your analyses. If you do not think that casing will be important for your task, it is likely better to select an *uncased* model because it comprises fewer words (e.g., happy and Happy are not two different words); thus, has had the chance to learn more high-quality embeddings.

**Sequence Length of the Input.** You can only impute a limited amount of text (tokens) to many language models at the time. For the BERT model the standard limit is 512 tokens at a time. This means that each word can be contextually influenced by a maximum of 511 tokens. If longer sequences of text are submitted to the *text-package* function, the text will be split up in smaller chunks; and then the word embeddings may be aggregated to represent the entire text.

**Tokens and Tokenizers.** A token is a string of characters with a meaning; and a tokenizer is a function that splits up sentences and words to tokens. Tokenizers may differ across models. Each token gets its own embedding. Common words are tokenized as themselves, whereas uncommon words that are not part of a pretrained model will be tokenized into smaller parts each having their own embedding. Punctuation characters (e.g., “.” “!” and “?”) also tend to get tokenized as individual tokens. BERT also uses tokens to indicate delimiter to each input: [CLS] and [SEP]. The [CLS] token is always put to indicate the start of the sequence and it is often used to represent the whole sequence. The [SEP] token stands for *separator*, and this tag is used to separate sentences during the pretraining tasks of BERT that include predicting the next sentence.

As an example, the sentence: “I’m feeling relatedness with others” is tokenized to “[CLS] I’m feeling related ##ness with others [SEP]”; where “##” indicates that “ness” was originally attached to “related.” “Relatedness” was tokenized this way because it was not present within (this version of) BERT. Instead, the two-word embeddings for “related” and “ness” are aggregated to represent relatedness.

**Layers.** To select the type of model and number of layers may be based on systematic, empirical research. Two systemic studies evaluating different transformers models found that RoBERTa (Liu et al., 2019) consistently performs better than BERT on *human-level* tasks (e.g., predicting characteristics of the person that authored a text) including predicting the demographics (age, gender), personality (extraversion, openness) and mental health (suicide risk) of individual based on their text (Ganesan et al., 2021; Matero et al., 2021). For human level tasks, using the four last layers or the second to last layer have

generally been found to yield good results; but recently Matero et al. (2021) more carefully examined which layer(s) that produce most accurate results in predicting depression related measures, which suggested that “layer 19 (sixth-to last) is the most ideal by itself” (p. 1).

**Limitations of Transformers.** Transformer models are very large. While researchers have developed ways to shrink models, the best versions of these models are still scaling exponentially. That is, the size of the files defining the models that users need is increasing more rapidly than the performance gains. While BERT-base comprises 110M parameters and achieves a Spearman rho of .86 on a standard semantic similarity task, BERT-large is approximately three times that size comprising 336M and achieves only a modest improvement in the same task:  $\rho = .87$ . With costs of storage and memory fairly inexpensive today, it may often be more ideal to use the larger models at the expense of needing better computing equipment, but this could exclude users with more limited computing resources. Further, it is very expensive to create your own model.

## Functions: Mapping Text to Numbers (i.e., Word Embeddings)

The *text-package* includes three functions to map text to word embeddings. The *textEmbed()* is a high-level function that encompasses both *textEmbedRawLayers()* and *textEmbedLayerAggregation()*. The *textEmbedRawLayers()* function retrieves layers and hidden states from the language model; and the *textEmbedLayerAggregation()* function aggregates these layers to form word embeddings. It is possible to get both contextualized and decontextualized embeddings for individual words (i.e., where only one word at a time has been sent to the model).

### *textEmbed()*

The *textEmbed()* function automatically transforms character variables in a given dataset (i.e., a dataframe or a tibble) to word embeddings. It is the main embedding function in *text*; and can output contextualized (and decontextualized) embeddings for tokens (i.e., the embeddings for each single *word* instance of each text) and texts (i.e., single embeddings per text taken from aggregating all token embeddings of the text).<sup>2</sup>

```
# Example text
texts <- c("I'm feeling relatedness with
others", "That's great!")

# Defaults
embeddings <- textEmbed(texts)

# Output
embeddings$tokens
```

<sup>2</sup> “Words” are defined by how the tokenizer breaks up the text string into individual units, often called unigrams. These may not always reflect what are conventionally called “words.” See <https://huggingface.co/docs/tokenizers/index> for a description of the different tokenizers available from HuggingFace’s transformers package.

## The Language Model

The pretrained language model is set with the *model setting* in `textEmbed()` (or `textEmbedRawLayers()`). The default model is “*bert-base-uncased*,” and other models can be specified by using their HuggingFace identifier (<https://huggingface.co/models>) such as “*roberta-base*” (Liu et al., 2019), “*distilbert-base-uncase*” (Sanh et al., 2019), or “*gpt2*” (Radford et al., 2019). When running a language model for the first time, the *text*-package automatically downloads it using the python package *transformers*. The files necessary to run a model are cached in a subdirectory of the user’s home directory called `.cache`. Subsequent calls to text methods that use the same model will directly access the model in cache rather than downloading it again. The `textModels()` function lists models and tokenizers that you have downloaded, and `textModelsRemove(“model-name”)` enables you to delete specific models and its accompanying files.

This tutorial uses example data that is accessible through the *text*-package. It is a subset from a study (see Kjell et al., 2019) where participants have described their satisfaction with life and harmony in life (or lack thereof) with a text response, 10 descriptive words or rating scales including the Satisfaction with Life Scale (SWLS; Diener et al., 1985) and the Harmony in Life Scale (HILS; Kjell et al., 2016). To embed text and build predictive models takes time. Embedding the included text examples takes approximately 10 min using a standard laptop. Word embeddings and models for the tutorial have been saved as part of the open tutorial data, so it is possible to follow the tutorial without running the most time-

consuming functions (note that it is possible to speed up the embedding process with access to graphics processing units, GPU).

## The Layers

The `textEmbed()` function has the *layers* parameter for selecting the layer(s) to extract (default = the second to last layer). The function also provides parameters to aggregate the layers in different ways: the *aggregation\_from\_layers\_to\_tokens* parameter controls how to aggregate layers representing the same token (default = “concatenate”). The *aggregation\_from\_tokens\_to\_texts* parameter controls how embeddings from different tokens should be aggregated to represent a text (default = “mean”). These defaults follow conventions from Natural Language Processing literature using transformers for regression and classification (Ganesan et al., 2021).

```

# Look at example data included in the text-package
  comprising both text and numerical variables (note that
  there are only 40 participants in this example).
  Language_based_assessment_data_8

# Transform the text/word data to word embeddings
  (see help(textEmbed) to see the default settings).
word_embeddings <- textEmbed(
  Language_based_assessment_data_8,
  model = "bert-base-uncased",
  aggregation_from_layers_to_tokens = "concatenate",
  aggregation_from_tokens_to_texts = "mean",
  keep_token_embeddings = FALSE
)

# See how the word embeddings are structured
word_embeddings

# Save the word embeddings to avoid having to embed the
  text again. It is good practice to save output from
  analyses that take a lot of time to compute, which is
  often the case when analyzing text data.
saveRDS(word_embeddings, "word_embeddings.rds")

# Get the saved word embeddings (again)
word_embeddings <- readRDS("word_embeddings.rds")

```

Note that one of the output layers is referred to as layer 0, which is the original input embedding to BERT; and hence, it is not contextualized.

`textEmbedRawLayers()`. The `textEmbedRawLayers()` takes text as input, and returns the hidden states for each token of the text, including the [CLS] and the [SEP]. This gives you more control over the embedding process compared with the `textEmbed()`. The output below shows the hidden states of layer 11 and 12 for each word/token of “I am fine” (i.e., `textEmbedRawLayers()` returns the layers in its raw form rather than aggregating them, which is the default in `textEmbed()`).

```

# Get hidden states for "I am fine"
imf_embeddings_11_12 <- textEmbedRawLayers(
  "I am fine",
  layers = 11:12
)
imf_embeddings_11_12

```

```
# OUTPUT

**textEmbedLayerAggregation().** The `textEmbedLayerAggregation()` function aggregates the hidden states from `textEmbedRawLayers()`. It is possible to select different methods for how layers and tokens are aggregated. The returned object is a word embedding that represents the entire text. Below we show how to (a) aggregate hidden states by concatenating layers 11 and 12, and computing the mean of each dimension across tokens (yielding a word embedding with 1,536 dimensions); and (b) only selecting layer 11 and computing the mean across tokens (yielding a word embedding with 768 dimensions).

```
# 1. Concatenate layers (results in 1,536 dimensions) .
textEmbedLayerAggregation(
  imf_embeddings_11_12$textcontext_tokens,
  layers = 11:12,
  aggregation_from_layers_to_tokens = "concatenate",
  aggregation_from_tokens_to_texts = "mean"
)
# OUTPUT

```

These word embeddings can be used for many different purposes and kinds of analyses. As such, the *text-package* serves R-users as a point solution for transforming text to state-of-the-art word embeddings that are ready to be used for their specific tasks. The next part of the tutorial exemplifies how word embeddings may be used and how the *text-package* may serve as an end-to-end solution that provides AI techniques tailored for social and behavioral scientists.

## Predictive Modeling With Word Embeddings

A common use of word embeddings is as input for statistical learning based predictive modeling (also known as machine learning). In such work for psychology, one often attempts to “predict” a score for a standard psychological assessment from language use (Kjell et al., 2021; Park et al., 2015). While there are endless types of predictive models from statistical learning in which one could input embeddings (see James et al., 2021, for a good introduction) numerous recent empirical studies have demonstrated that when using modern contextual embeddings, L2-penalized linear models yield state-of-the-art results (Ganesan et al., 2021; Kjell et al., 2022; Matero et al., 2019). For example, Matero et al. (2019) used L2 regularized logistic regression on top of transformer-based contextual embeddings to achieve top results on the computational linguistics for psychology 2019 Shared task B (“CLPsych-2019”; Zirikly et al., 2019), which compared 28 predictive systems, using techniques varying from convolutional neural networks (CNNs) to random forests or multilayer perceptrons, from 11 participating teams. Shared tasks are particularly robust evaluations because the system designers are not giving the true labels but rather, they send their predictions based on text without labels to a third party that runs the evaluation and reports the accuracies. Many other recent shared tasks have similarly confirmed systems with L2 penalized linear models on top of contextual embeddings to be among the best performing, such as a BERT-based system for the SemEval-2020 task on sentiment analysis (Palomino & Ochoa-Luna, 2020) or a system combining multiple contextual embeddings via an L2 penalized linear regression (“ridge regression”) layer for the SemEval-2020 task on humor detection (Hossain et al., 2020; Morishita et al., 2020).<sup>3</sup> These works support the idea that because transformer-based contextual embeddings produce state-of-the-art semantic representations of text itself, sophisticated models on top of them are not necessary (and sometimes overfit) for producing accurate predictions (Bommasani et al., 2021). Next, we describe how these techniques are used in more detail.

<sup>3</sup> Note that in many modern NLP papers and deep learning packages, an L2 penalization is referred to as “weight decay.”

## Word Embeddings as Input to a Predictive Model

The word embeddings may be used in predictive models such as multiple linear regression:

$$y = \beta_0 + \beta_1 * x_1 \dots + \beta_m * x_m + \varepsilon$$

where  $y$  denotes the observed values (in which  $\hat{y}$  represents the predicted value),  $x_1 \dots x_m$  the predictors, i.e., the dimensions of the word embeddings (where the subscript refers to the  $m^{\text{th}}$  dimension),  $\beta_0$  the constant,  $\beta_1 \dots \beta_m$  the coefficients that define the relationship between embeddings and the outcome, and  $\varepsilon$  the error term.

Considering that the word embeddings often comprise many dimensions, it is often useful to first carry out a dimension reduction technique. To achieve this, Principal Component Analysis (e.g., see Wold et al., 1987) is implemented in *text* because we have noticed that it is particularly efficient for reducing the dimensionality of word embeddings. It is possible to select other statistical prediction models in *text*, including using ridge (L2 penalized) regression by itself (Hoerl & Kennard, 1970), lasso regression (also called L1-penalized model; Tibshirani, 1996), or a mix of L1 and L2-penalized regression (i.e., “elastic-net” regression; Zou, & Hastie, 2005) and for categorical variables ridge-penalized logistic regression or random forests (e.g., see Ho, 1995). Although *text* supports lasso and elastic-net (the latter is a composite of both a lasso and ridge penalty), it is worth noting that the top systems in the previously mentioned tasks use only a ridge penalty (Matero et al., 2019), which is also the default in the most popular contextual embedding library, transformers (controlled with the “weight\_decay” in the pytorch library it utilizes). This lack of utilization for dense embeddings is probably because any regularization involving a lasso is designed for sparse input information (Ganguli & Sompolinsky, 2012), which is not present in most embeddings. Embeddings are typically dense and rotationally invariant. In other words, singular dimensions do not necessarily correspond to distinct sets of words. On the other hand, for nondense input vectors, such as with dimensions corresponding to counts of particular words—a multihot encoding or word count vector—the lasso has been found beneficial (Schwartz et al., 2013).

## Cross Validation

To evaluate the predictions made by a statistical model, it is possible to correlate the predicted values with the observed values (i.e.,  $\text{cor}[y, \hat{y}]$ ) using cross-validation. Cross validation is a technique that may be used to evaluate and select a statistical model with minimal overfit (for a more detailed discussion on cross validation in psychology, e.g., see Mosier, 1951; Yarkoni & Westfall, 2017). Overfitting arises when data-specific errors or noise are modeled, which results in a model that is bad at generalizing to other data. The cross-validation methods aim to limit this risk by estimating a

model’s predictive ability while simultaneously accounting for its ability to generalize (e.g., see Browne, 2000). The simplest form of a cross validation method randomly divides a dataset into a *training-set* and a *testing-set*. The parameters, that is, the  $\beta_1 \dots \beta_m$  in the specified regression above, are estimated in the training-set; and then applied to the test-set to predict values ( $\hat{y}$ ) that can be compared with the observed values ( $y$ ). Using this method results in an *out-of-sample performance*, where the trained model is applied on new data from the same population.

## K-Fold Cross Validation

K-fold cross validation is a procedure to divide the training and testing sets efficiently. If data are scarce, it may be considered wasteful to not use all data, for example, to only use 50% of the data for training and 50% only for testing. First, it is possible to run the procedure again by alternating the purpose of the data sets, so that the original testing-set becomes the training-set, and the original training-set becomes the testing-set: In this way all data will have predictions that can be correlated with the observed values. Second, to make better parameter estimations it is possible to get more power in the statistical models by making sure that the training set is larger. One common way is to select 90% of the data to the training set and 10% for the testing; and then alter the purpose of the data as previously described. This is done ten times, so that all cases get a prediction. Hence,  $k$  in  $k$ -fold refers to the number of groups (or folds); so, the described procedure is called 10-fold cross validation. It is also possible to train on all but one case (that is called *leave-one-out* cross validation). Leave-one-out cross validation is good for very small dataset, whereas for larger dataset it requires a lot of computational power and time (for rather small gains).

### Cross Validation With Test, Train, and Development Sets.

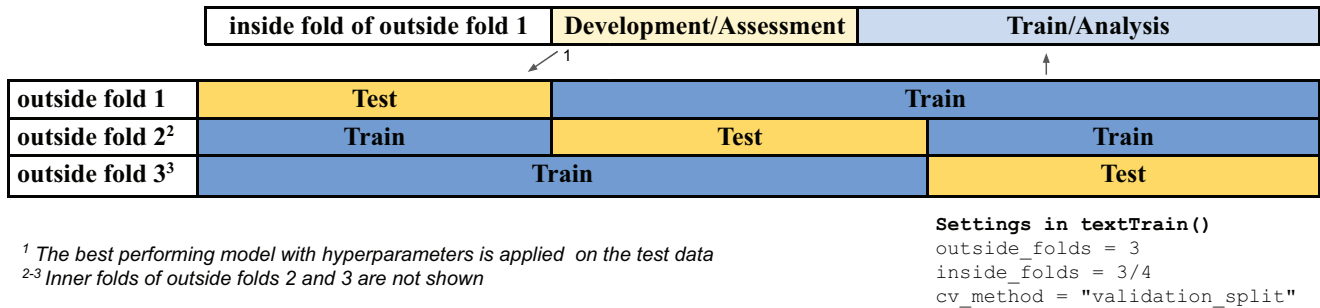

The word embeddings may be used in predictive models such as multiple linear regression:

$$y = \beta_0 + \beta_1 * x_1 \dots + \beta_m * x_m + \varepsilon$$

where  $y$  denotes the observed values (in which  $\hat{y}$  represents the predicted value),  $x_1 \dots x_m$  the predictors, i.e., the dimensions of the word embeddings (where the subscript refers to the  $m^{\text{th}}$  dimension),  $\beta_0$  the constant,  $\beta_1 \dots \beta_m$  the coefficients that define the relationship between embeddings and the outcome, and  $\varepsilon$  the error term.

**Nested K-Fold Cross Validation.** To use nested cross validation, including train and test loops in the inner fold of each outside fold, is also a way to make better use of the data (see Figure 3). The above cross validation method with test, train and development sets focuses on achieving more accurate estimates of the machine learning approach, which is good when comparing machine learning algorithms. The nested  $k$ -fold cross validation focuses on achieving a

**Figure 2**  
*Cross Validation With Three Outside Folds; and  $\frac{3}{4}$  Analysis and  $\frac{1}{4}$  Development Set*

*Note.* See the online article for the color version of this figure.

more accurate model; but tends to take longer time because more models need to be fitted and evaluated.

**Applying Predictive Models to New Data**

Language-based predictive models can be applied to new data. Independently trained language models may be applied to new data to examine semantic-psychological features such as valence or arousal. It is also easy to share predictive models between projects and researchers. For example, it is possible to develop predictive models for valence and arousal, based on the Affective norms for English Words (ANEW; Bradley & Lang, 1999). The ANEW is a list of more than 1,000 words that have been rated according to valence, dominance, and arousal by participants. A valence model can be created by predicting valence from the word embeddings of the words in the list. First the model can be evaluated using cross validation to see how good it is; and then it can be saved without using cross validation to use all the data. This model can now be used to estimate the valence of any word or set of text represented by a word embedding based on the same language model (and settings) originally used to create the word embeddings in the predictive model. Hence, it is a flexible method considering that it is possible

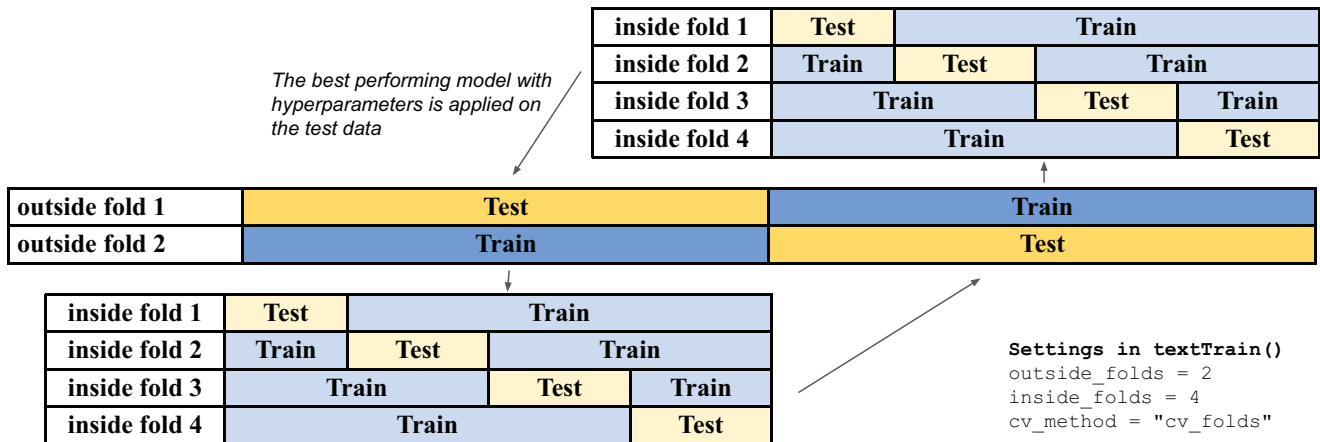

to get predictions for words that were not in the original model/ words list, since the estimated parameters are applied to the dimensions of the word embeddings.

**Functions**

**textTrain().** The `textTrain()` function is used to examine how well the word embeddings from a text can predict a numeric or categorical variable, based on the different cross-validation methods described above. The `textTrain()` function is a wrapper for `textTrainRegression()` and `textTrainRandomForest()`. In the example below we examine how well the satisfaction text-responses can predict the rating scale scores from the Satisfaction with life scale. We advise researchers to share their predictive models, for example, on their Open Science Framework account (<https://osf.io/>) or GitHub. For this purpose, it is possible to attach a description of the data and model by describing it in the `describe_model` setting. For example, use the following format:

```
model_description = "author(s): XXX; data: N = XXX, population = XXX; publication: title = XXX; description: e.g., measure details etc."
```

**Figure 3**  
*Example of Nested Cross Validation With Two Outside Folds and Four Inside Folds*

*Note.* Prioritizing more outside than inside folds makes often more sense. See the online article for the color version of this figure.

This document is copyrighted by the American Psychological Association or one of its allied publishers. This article is intended solely for the personal use of the individual user and is not to be disseminated broadly.

```
# Examine the relationship between satisfactiontext and

#OUTPUT:

[1] "predictions"
[2] "final_recipe"
[3] "final_model"
[4] "model_description"
[5] "results"
```

The returned output from training includes: (a) the cross-validated *predictions* with the observed values and row id; (b) the *final "recipe"* with information about how to preprocess the data before using it for training/prediction; (c) the *final model with* model information, which can be used for prediction, (d) the *model description* contain information about the options used to create the model as well as the information added by the user; and (e) the *results* including a comparison between cross-validated predictions and observed values/categories. The result for numeric values is by default a *Pearson* correlation, which can be changed with `method_cor`. The results for a classification task include a Fisher's Exact test for Count Data, Pearson's chi-square test with Yates' continuity correction, a plotted ROC curve and metrics from the R-package *yardstick* (Kuhn & Vaughan, 2020b) including accuracy, balanced accuracy (`bal_accuracy`), specificity (`spec`), sensitivity (`sens`), and kappa (`kap`).

**textTrainLists()**. The `textTrainLists()` runs through several text variables (i.e., lists of word embeddings) and/or numeric variables at the same time.

```
# Predicting several outcomes from several word embeddings

## Computing Semantic Similarity and Distance

Word embeddings may be used to measure how similar two words/texts are in meaning. The values composing a word embedding may be seen as coordinates in a high dimensional space; and the more similar two embedding vectors are the closer they are positioned in the space. There are many ways to capture how closely positioned two vectors are; in *text* many common similarity and distance measures can be used, including “cosine,” “euclidean,” “maximum,” “manhattan,” “canberra,” “binary,” or “minkowski” (for a review of similarity measures see Chandrasekaran & Mago, 2022). The default similarity measure in *text*, is to measure the cosine of the angle between them (see a simplified illustration in Figure 4).

Similar to a correlation, the cosine can range from  $-1$  to  $1$  (see Wickens, 2014, for a discussion on how correlation and cosine are mathematically related); but in the embedding space the cosine between two words is typically not much below 0. The smaller the angle, the higher the cosine is, and thus, the more similar are the embeddings (this cosine measure is referred to as a semantic similarity score).

The cosine may be seen as an unstandardized effect size indicating the strength of a relationship (Charikar, 2002); however, it should be noted that its absolute value is not comparable between different models and model specification setups. For example, Ethayarajh (2019) demonstrated that word embeddings have different distributions in different BERT layers, so that two random words on average tend to have higher cosine similarity in higher as opposed to lower layers. Thus, comparing two cosine based semantic similarity scores between two different models or layers is not interpretable; instead examine the relative difference in scores from the same model/layer(s).

## Functions: *textSimilarity()* and *textDistance()*

The *textSimilarity()* function computes the semantic similarity between two embeddings, and the *textSimilarityNorm()* computes the semantic similarity between one text variable and a word norm. We also provide corresponding *textDistance()* and *textDistanceNorm()* functions that compute the distance between the vectors rather than the similarity (i.e., greater value indicates more difference rather than more similarity). For *textDistance()* the default is euclidean distance, and for *textSimilarity()* the default is cosine similarity. Semantic similarity scores can, for example, be used to measure psychological constructs independent from rating scales by using word norms that represent the to-be-measured construct (Kjell et al., 2019). A word norm can be created by asking participants to describe a psychological construct. The word norm can be

**Figure 4**  
Illustration of the Semantic Similarity of Two Words in a Simplified Two-Dimensional Embedding Space

*Note.* This also holds when adding many more dimensions.

used to measure the semantic similarity between a person’s answer to whether they experience harmony in their life to the word norm describing harmony in life: If the score is high the person is seen to have high harmony in life. Below this analysis is described.

```
# Compute semantic similarity scores between two text columns,
using the previously created word_embeddings.

### Extended Functionality

In addition to implementations of standard analyses of text (the functions listed above), *text* comes with several less established novel functions. These are intended to support the core functionalities (and overtime become more empirically evaluated).

### Words' Position in the Embedding Space

There are many different ways to visualize the words in a data set such as multidimensional scaling (MDS; e.g., Borg & Groenen, 2005), t-Distributed Stochastic Neighbor Embedding (t-SNE; Van der Maaten, & Hinton, 2008) and Principal Component Analysis (PCA; see Appendix for the *text* functions *textPCA()* and *textPCA-Plot()*). Here we will briefly demonstrate two plot functions in *text* for demonstrating potential basic uses of the word embeddings: The Supervised Dimension Projection Plot shows words that are significantly related to one compared with another group, where the test statistics are tested in permutation test procedures. The Semantic Centrality Plot shows the words that are most semantically central to a set of texts/words. Both functions plot the words' position based on their word embeddings.

### The Supervised Dimension Projection

The Supervised Dimension Projection compares two groups (e.g., intervention versus nonintervention participant), responses to different questions (e.g., harmony versus satisfaction responses), or low versus high scorers on a rating scale using median split or lower/higher quartiles. In short, we construct an embedding that captures the difference between the two groups, a vector that forms a line through the origin (the *aggregated direction embedding*); then all individual words are "projected" onto that direction line (where dot product is computed to "project" a vector onto another

vector; see Figure 5 for a visualization). More precisely, the plot is based on the following steps:

#### Preprocessing.

1. Responses are divided into two groups (G1 and G2; where a scale variable is split according to mean or lower and higher quartile).
2. The aggregated word embeddings of the two groups are computed: The G1 split aggregation embedding and the G2 split aggregation embedding.

#### Supervised dimension projection statistics.

3. An Aggregated direction embeddings is computed: *Aggregated direction embeddings* = G2 split aggregation embedding – G1 split aggregation embedding.

So, for example, the direction of harmony = Group(high harmony) – Group(low harmony); where the direction is seen to go through the origin and the aggregated direction embedding.

4. All individual word embeddings are positioned (or anchored) to the same point. So, for each word: *Anchored embedding* = original embedding – aggregation embedding of G1 and G2 from Step 2.
5. To project onto the *Aggregated direction embeddings* (i.e., from Step 3), the dot product is computed between the *Anchored embedding* of all individual words (i.e., from Step 4) and the *Aggregated direction embeddings* (i.e., Step 3). That is, dot product(*Anchored we*, *Aggregated direction we*) = a point on the direction.

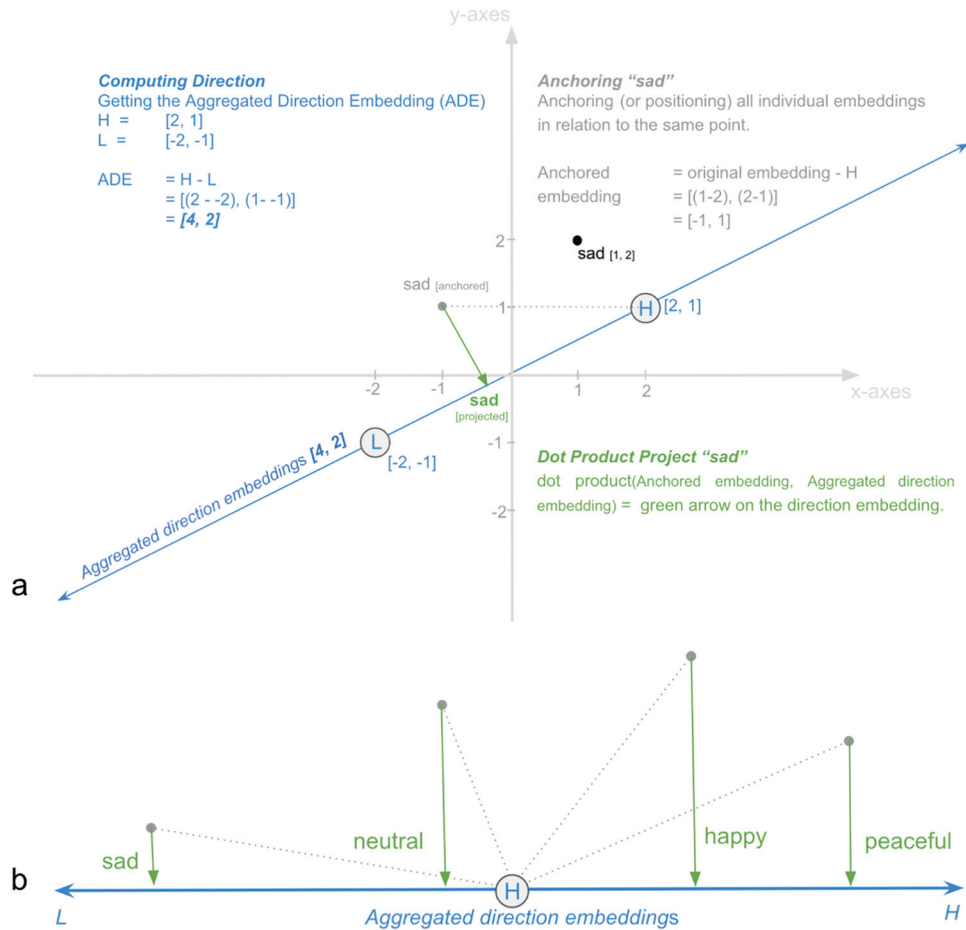

#### Computing *p*-values with a permutation procedure.

6. A permuted null distribution of Supervised Dimension Projections is created by computing the dot product between randomly selected word embeddings from G1 and G2, and a Permuted aggregated direction embeddings (i.e., the direction embedding is also created by randomly swapping words from G1 and G2).
7. The *p*-values for each word are computed by comparing their Supervised Dimension Projection with the permuted null distribution of Supervised Dimension Projections from Step 6, as in previous descriptions; while correcting for multiple comparisons according to selected methods.

### Functions

The plotting is made with two functions, in two steps: First, *textProjection()* analyzes the data, including Supervised Dimension Projections, null distributions, *p*-values, and frequencies. Second, *textProjectionPlot()* uses the output from *textProjection()* to plot the words, including providing design options for the figure. Dividing the plotting procedure into these two steps makes the process more transparent (i.e., the user naturally sees the output according to which the words will be plotted) as well as being more flexible by enabling the user to try

**Figure 5**  
Illustrations of the Supervised Dimension Projection Method

Note. The illustration exemplifies the reduction of two dimensions to one dimension, where in practice there are many more dimensions. See the online article for the color version of this figure.

out different visual settings without the need to rerun the heavy computational processes.

To plot words, each individual word type needs to be represented by an embedding: a word type embedding (i.e., a single embedding per word type taken from aggregating token embeddings across all instances of all word types in the given data).<sup>4</sup> In `textEmbed()` the optional setting `aggregation_from_tokens_to_word_types`, controls how the word types embeddings are aggregated (default = "mean").

**textProjection().**

```
# Extract word type embeddings and text embeddings for
harmony_words
harmony_words_embeddings <- textEmbed(
  texts = Language_based_assessment_data_8["harmonywords"],
  aggregation_from_layers_to_tokens = "concatenate",
  aggregation_from_tokens_to_texts = "mean",
  aggregation_from_tokens_to_word_types = "mean",
  keep_token_embeddings = FALSE
)
```

```
# Pre-processing data for plotting
projection_results <- textProjection(
  words = Language_based_assessment_data_8$harmonywords,
  word_embeddings = harmony_words_embeddings$texts,
  word_types_embeddings = harmony_words_embeddings$word_types,
  x = Language_based_assessment_data_8$hiltotal,
  y = Language_based_assessment_data_8$age
)
projection_results$word_data
```

<sup>4</sup> Word "types" refers to a word in general as opposed to a word "token" that refers to a specific instance of a word. For example, in "The horse raced past the other horse" the word type "horse" appears twice: as the second- and seventh-word tokens. Each token for horse can have a different embedding so to get a single embedding for the word type, "horse," they must be aggregated in some way. For noncontextual embeddings that are always the same for the same word, all one has, technically, are embeddings of the word type and not the specific instance (tokens).

```
# PART OF OUTPUT
  words      dot.x      p_values_dot.x
<chr>      <dbl>      <dbl>

**Figure 6**  
A One-Dimensional Plot From textProjectionPlot()

Note. DPP = Dot Product Projection. The dots represent the point for visible words. See the online article for the color version of this figure.

This document is copyrighted by the American Psychological Association or one of its allied publishers. This article is intended solely for the personal use of the individual user and is not to be disseminated broadly.

**Figure 7**  
A Two-Dimensional Plot From `textProjectionPlot()`

*Note.* A supervised dimension projection plot of words significantly differing between low versus high harmony in life scale score (x-axis) and low versus high age (y-axis). The font size of the words indicates their frequency. The color indicates whether a word is significant or not significant (gray) when correcting for multiple comparisons using the false discovery rate (FDR). The color-legend in the lower left corner indicates the color and number of significant words in each part of the figure (e.g., there are 18 light green words that are significantly high on the x-axis and low on the y-axis). The dots represent the point for visible words. The values on the x- and y-axes represent the dot product projection value (these should be compared with caution between figures); DPP = Dot product projection. See the online article for the color version of this figure.

**Words’ Semantic Centrality**

The Semantic Centrality Plot aims to highlight words that are semantically similar to the aggregated word embeddings of all words in the given text variable. Hence, it describes the psychological construct or latent meaning of a text under investigation in the word embedding space. The aim is to highlight words from one type of response, rather than comparing two groups/dimensions. The statistics are computed with the `textCentrality()` function. This is achieved in the following steps:

1. Computing the *Aggregated word embedding (Awe)* based on all words.
2. Computing the observed semantic similarity scores between individual word’s embeddings (Iwe) and the aggregated word embedding (Awe).  
 $\cos(Iwe, Awe) = \text{semantic similarity score}$

Using the `textCentralityPlot()` it is possible to select the most extreme semantic centrality scores, middle scores as well as selecting words based on their frequency.

**Functions**

```
# Computing words' centrality (semantic similarity) score
to the aggregated embedding of all words
centrality_results <- textCentrality(
  words = word_norms$satisfactionnorm,
  word_embeddings = word_norms_embeddings$texts
  $satisfactionnorm,
```

```
word_types_embeddings = word_norms_
embeddings$word_types
)
centrality_plot <- textCentralityPlot(
  word_data = centrality_results,
  min_freq_words_test = 2,
  plot_n_word_extreme = 10,
  plot_n_word_frequency = 5,
  plot_n_words_middle = 5,
  title_top = "Satisfaction with life word norm:
  Semantic Centrality Plot",
  x_axes_label = "Satisfaction with Life
  Semantic Centrality"
)
# View plot (see Figure 8)
centrality_plot$final_plot
```

**Summary**

The `text`-package has two main aims: First, to work as a modular solution for transforming text to state-of-the-art word embeddings for R-users. Second, to work as an end-to-end solution focusing on relevant functions for social sciences and human-level analyses. It is our hope that the `text`-package can increase the ability of psychological scientists to analyze, with state-of-the-art computational techniques, one of the fundamental and key behaviors of people: natural language.

(Appendix follows)

## Appendix PCA Plot

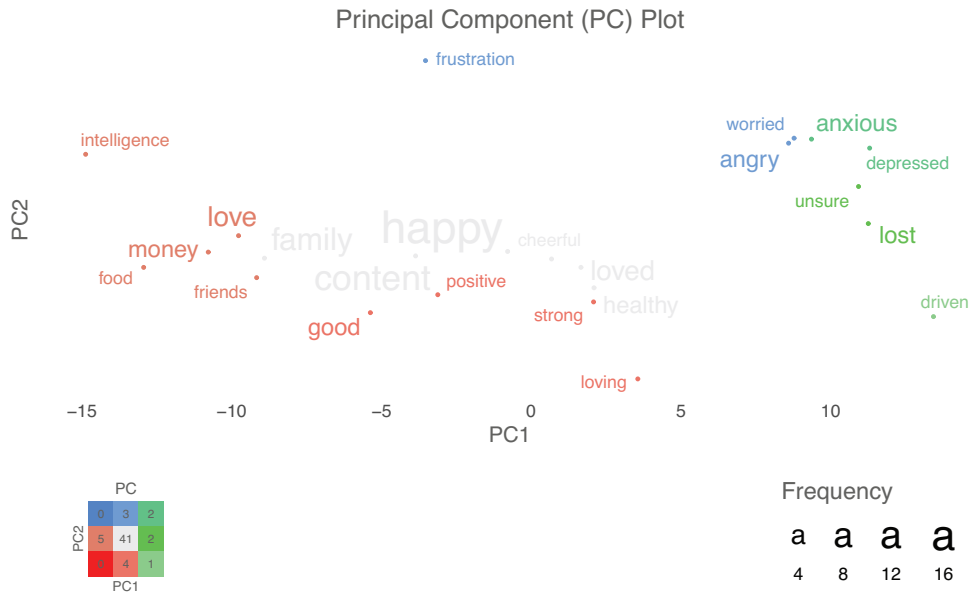

To create a traditional two-dimensional Principal Component Analysis plot, it is possible to use `textPCA` and `textPCAPlot`.

```
# PCA results to be plotted
textPCA_results <- textPCA(
  words = Language_based_assessment_data_8$satisfactionwords,
  word_types_embeddings = harmony_words_embeddings$word_types
)

# Plotting the PCA results
plot_PCA <- textPCAPlot(
  word_data = textPCA_results,
  min_freq_words_test = 2,
  plot_n_word_extreme = 5,
  plot_n_word_frequency = 5,
  plot_n_words_middle = 5
)

# View plot (see Figure A1)
plot_PCA$final_plot
```

**Figure A1**  
A plot from `textPCA()`

*Note.* See the online article for the color version of this figure.
